
CS 61A Structure and Interpretation of Computer Programs

Fall 2014

MIDTERM 2

INSTRUCTIONS

- You have 2 hours to complete the exam.
- The exam is closed book, closed notes, closed computer, closed calculator, except one hand-written 8.5" × 11" crib sheet of your own creation and the 2 official 61A midterm study guides attached to the back of this exam.
- Mark your answers ON THE EXAM ITSELF. If you are not sure of your answer you may wish to provide a *brief* explanation.

1. (12 points) Class Hierarchy

For each row below, write the output displayed by the interactive Python interpreter when the expression is evaluated. Expressions are evaluated in order, and **expressions may affect later expressions**.

Whenever the interpreter would report an error, write ERROR. You *should* include any lines displayed before an error. *Reminder*: The interactive interpreter displays the **repr** string of the value of a successfully evaluated expression, unless it is **None**. Assume that you have started Python 3 and executed the following:

```
class Worker:
    greeting = 'Sir'
    def __init__(self):
        self.elf = Worker
    def work(self):
        return self.greeting + ', I work'
    def __repr__(self):
        return Bourgeoisie.greeting
class Bourgeoisie(Worker):
    greeting = 'Peon'
    def work(self):
        print(Worker.work(self))
        return 'My job is to gather wealth'
class Proletariat(Worker):
    greeting = 'Comrade'
    def work(self, other):
        other.greeting = self.greeting + ' ' + other.greeting
        other.work() # for revolution
        return other
jack = Worker()
john = Bourgeoisie()
jack.greeting = 'Maam'
```

Expression	Interactive Output	Expression	Interactive Output
5*5	25	john.work()[10:]	
1/0	ERROR		
Worker().work()			
jack		Proletariat().work(john)	
		john.elf.work(john)	
jack.work()			

2. (14 points) Space

(a) (8 pt) Fill in the environment diagram that results from executing the code below until the entire program is finished, an error occurs, or all frames are filled. *You may not need to use all of the spaces or frames.*

A complete answer will:

- Add all missing names and parent annotations to all local frames.
- Add all missing values created during execution.
- Show the return value for each local frame.

```

1 def locals(only):
2   def get(out):
3     nonlocal only
4     def only(one):
5       return lambda get: out
6       out = out + 1
7       return [out + 2]
8   out = get(-only)
9   return only
10
11 only = 3
12 earth = locals(only)
13 earth(4)(5)

```

Global frame	
locals	
only	3

func locals(only) [parent=Global]

f1: _____	[parent=_____]
Return Value	

f2: _____	[parent=_____]
Return Value	

f3: _____	[parent=_____]
Return Value	

f4: _____	[parent=_____]
Return Value

- (b) (6 pt) Fill in the blanks with the shortest possible expressions that complete the code in a way that results in the environment diagram shown. You can use only brackets, commas, colons, and the names `luke`, `spock`, and `yoda`. You ***cannot*** use integer literals, such as 0, in your answer! You also cannot call any built-in functions or invoke any methods by name.

```

spock, yoda = 1, 2

luke = [_____]

yoda = 0

yoda = [_____]

yoda.append(_____)

```

3. (8 points) This One Goes to Eleven

- (a) (4 pt) Fill in the blanks of the implementation of `sixty_ones` below, a function that takes a `Link` instance representing a sequence of integers and returns the number of times that 6 and 1 appear consecutively.

```
def sixty_ones(s):
    """Return the number of times that 1 directly follows 6 in linked list s.

    >>> once = Link(4, Link(6, Link(1, Link(6, Link(0, Link(1))))))
    >>> twice = Link(1, Link(6, Link(1, once)))
    >>> thrice = Link(6, twice)
    >>> apply_to_all(sixty_ones, [Link.empty, once, twice, thrice])
    [0, 1, 2, 3]
    """
    if -----:

        return 0

    elif -----:

        return 1 + -----
    else:

        return -----
```

- (b) (4 pt) Fill in the blanks of the implementation of `no_eleven` below, a function that returns a list of all distinct length-`n` lists of ones and sixes in which 1 and 1 do not appear consecutively.

```
def no_eleven(n):
    """Return a list of lists of 1's and 6's that do not contain 1 after 1.

    >>> no_eleven(2)
    [[6, 6], [6, 1], [1, 6]]
    >>> no_eleven(3)
    [[6, 6, 6], [6, 6, 1], [6, 1, 6], [1, 6, 6], [1, 6, 1]]
    >>> no_eleven(4)[:4] # first half
    [[6, 6, 6, 6], [6, 6, 6, 1], [6, 6, 1, 6], [6, 1, 6, 6]]
    >>> no_eleven(4)[4:] # second half
    [[6, 1, 6, 1], [1, 6, 6, 6], [1, 6, 6, 1], [1, 6, 1, 6]]
    """
    if n == 0:

        return -----

    elif n == 1:

        return -----

    else:

        a, b = no_eleven(-----), no_eleven(-----)

        return [----- for s in a] + [----- for s in b]
```

4. (8 points) Tree Time

- (a) (4 pt) A `GrootTree` g is a binary tree that has an attribute `parent`. Its parent is the `GrootTree` in which g is a branch. If a `GrootTree` instance is not a branch of any other `GrootTree` instance, then its `parent` is `BinaryTree.empty`.

`BinaryTree.empty` should not have a `parent` attribute. Assume that every `GrootTree` instance is a branch of at most one other `GrootTree` instance and not a branch of any other kind of tree.

Fill in the blanks below so that the `parent` attribute is set correctly. You may not need to use all of the lines. Indentation is allowed. You *should not* include any `assert` statements. Using your solution, the doctests for `fib_groot` should pass. The `BinaryTree` class appears on your study guide.

Hint: A picture of `fib_groot(3)` appears on the next page.

```
class GrootTree(BinaryTree):
    """A binary tree with a parent."""

    def __init__(self, entry, left=BinaryTree.empty, right=BinaryTree.empty):
        BinaryTree.__init__(self, entry, left, right)
```

Assignment Project Exam Help

<https://powcoder.com>

Add WeChat powcoder

```
def fib_groot(n):
    """Return a Fibonacci GrootTree.

    >>> t = fib_groot(3)
    >>> t.entry
    2
    >>> t.parent.is_empty
    True
    >>> t.left.parent.entry
    2
    >>> t.right.left.parent.right.parent.entry
    1
    """
    if n == 0 or n == 1:
        return GrootTree(n)
    else:
        left, right = fib_groot(n-2), fib_groot(n-1)
        return GrootTree(left.entry + right.entry, left, right)
```

- (b) (4 pt) Fill in the blanks of the implementation of `paths`, a function that takes two arguments: a `GrootTree` instance `g` and a list `s`. It returns the number of paths through `g` whose entries are the elements of `s`. A path through a `GrootTree` can extend either to a branch or its parent.

You may assume that the `GrootTree` class is implemented correctly and that the list `s` is non-empty.

The two paths that have entries `[2, 1, 2, 1, 0]` in `fib_groot(3)` are shown below (left). The one path that has entries `[2, 1, 0, 1, 0]` is shown below (right).

```
def paths(g, s):
    """The number of paths through g with entries s.

    >>> t = fib_groot(3)
    >>> paths(t, [1])
    0
    >>> paths(t, [2])
    1
    >>> paths(t, [2, 1, 2, 1, 0])
    2
    >>> paths(t, [2, 1, 0, 1, 0])
    1
    >>> paths(t, [2, 1, 2, 1, 2, 1])
    8
    """

    if g is BinaryTree.empty:
        return 0

    elif:

        return 1

    else:

        xs = [ ]

        return sum([ ] for x in xs)
```

5. (8 points) Abstraction and Growth

- (a) (6 pt) Your project partner has invented an abstract representation of a sequence called a **slinky**, which uses a **transition** function to compute each element from the previous element. A **slinky** explicitly stores only those elements that cannot be computed by calling **transition**, using a **starts** dictionary. Each entry in **starts** is a pair of an index key and an element value. See the doctests for examples.

Help your partner fix this implementation by crossing out as many lines as possible, but leaving a program that passes the doctests. Do not change the doctests. The program continues onto the following page.

```
def length(slinky):
    return slinky[0]
def starts(slinky):
    return slinky[1]
def transition(slinky):
    return slinky[2]

def slinky(elements, transition):
    """Return a slinky containing elements.

    >>> t = slinky([2, 4, 10, 20, 40], lambda x: 2*x)
    >>> starts(t)
    {0: 2, 2: 10}
    >>> get(t, 3)
    20
    >>> r = slinky(range(3, 10), lambda x: x+1)
    >>> length(r)
    7
    >>> starts(r)
    {0: 3}
    >>> get(r, 2)
    5
    >>> slinky([1, abs], abs)
    [0, {}, <built-in function abs>]
    >>> slinky([5, 4, 3], abs)
    [3, {0: 5, 1: 4, 2: 3}, <built-in function abs>]
    """
    starts = {}
    last = None
    for e in elements[1:]:
    for index in range(len(elements)):
        if not e:
            if index == 0:
                return [0, {}, transition]
            if last is None or e != transition(last):
            if e == 0 or e != transition(last):
            if index == 0 or elements[index] != transition(elements[index-1]):
                starts[index] = elements[index]
                starts[index] = elements.pop(index)
                starts[e] = transition(last)
                starts[e] = last
            last = e
    return [len(starts), starts, transition]
    return [len(elements), starts, transition]
    return [len(starts), elements, transition]
    return [len(elements), elements, transition]
```

    return value
    return f(value)

```

Assignment Project Exam Help

<https://powcoder.com>

(b) (2 pt) Circle the Θ expression below that describes the number of operations required to compute `slinky(elements, transition)`, assuming that

- n is the initial length of `elements`,
- d is the final length of the `starts` dictionary created,
- the `transition` function requires constant time,
- the `pop` method of a list requires constant time,
- the `len` function applied to a list requires linear time,
- the `len` function applied to a range requires constant time,
- adding or updating an entry in a dictionary requires constant time,
- getting an element from a list by its index requires constant time,
- creating a list requires time that is proportional to the length of the list.

Import statement

```
1 from math import pi
2 tau = 2 * pi
```

Assignment statement

Code (left):

Statements and expressions
Red arrow points to next line.
Gray arrow points to the line just executed

Frames (right):

A name is bound to a value
In a frame, there is at most one binding per name

```
1 from operator import mul
2 def square(x):
3     return mul(x, x)
4 square(-2)
```

Built-in function

User-defined function

Global frame

Intrinsic name of function called

Local frame

Formal parameter bound to argument

Return value

Return value is not a binding!

```
1 from operator import mul
2 def square(x):
3     return mul(x, x)
4 square(square(3))
```

Global frame

Local frame

Return value

A name evaluates to the value bound to that name in the earliest frame of the current environment in which that name is found.

Evaluation rule for call expressions:

1. Evaluate the operator and operand subexpressions.
2. Apply the function that is the value of the operator subexpression to the arguments that are the values of the operand subexpressions.

Applying user-defined functions:

1. Create a new local frame with the same parent as the function that was applied.
2. Bind the arguments to the function's formal parameter names in that frame.
3. Execute the body of the function in the environment beginning at that frame.

Execution rule for def statements:

1. Create a new function value with the specified name, formal parameters, and function body.
2. Its parent is the first frame of the current environment.
3. Bind the name of the function to the function value in the first frame of the current environment.

Execution rule for assignment statements:

1. Evaluate the expression(s) on the right of the equal sign.
2. Simultaneously bind the names on the left to those values, in the first frame of the current environment.

Execution rule for conditional statements:

Each clause is considered in order.

1. Evaluate the header's expression.
2. If it is a true value, execute the suite, then skip the remaining clauses in the statement.

Evaluation rule for or expressions:

1. Evaluate the subexpression <left>.
2. If the result is a true value v, then the expression evaluates to v.
3. Otherwise, the expression evaluates to the value of the subexpression <right>.

Evaluation rule for and expressions:

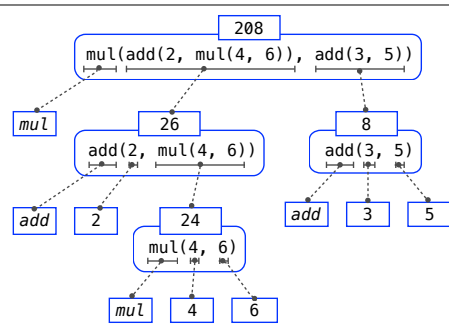

1. Evaluate the subexpression <left>.
2. If the result is a false value v, then the expression evaluates to v.
3. Otherwise, the expression evaluates to the value of the subexpression <right>.

Evaluation rule for not expressions:

1. Evaluate <exp>; The value is True if the result is a false value, and False otherwise.

Execution rule for while statements:

1. Evaluate the header's expression.
2. If it is a true value, execute the (whole) suite, then return to step 1.

Defining:

```
>>> def square(x):
    return mul(x, x)
```

    if x > 0:
        return x
    elif x == 0:
        return 0
    else:
        return -x
```

Higher-order function: A function that takes a function as an argument value or returns a function as a return value

Nested def statements: Functions defined within other function bodies are bound to names in the local frame

Global frame

Local frame

Return value

```
square = lambda x,y: x * y
```

A function

with formal parameters x and y
that returns the value of " $x * y$ "

Must be a single expression

Evaluates to a function.
No "return" keyword!

```
def make_adder(n):
```

A function that returns a function

```
    """Return a function that takes one argument k and returns k + n.
```

```
>>> add_three = make_adder(3)
```

```
>>> add_three(4)
```

The name `add_three` is bound to a function

```
7
```

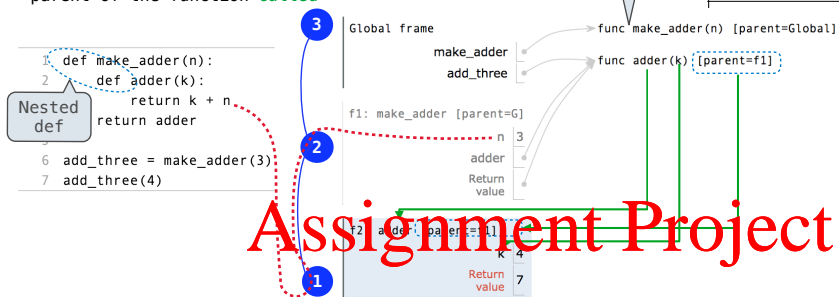

```
def adder(k):
```

```
    return k + n
```

```
    return adder
```

A local
def statementCan refer to names in
the enclosing function

- Every user-defined function has a **parent frame** (often global)
- The parent of a function is the frame in which it was **defined**
- Every local frame has a **parent frame** (often global)
- The parent of a frame is the parent of the function **called**

A function's signature
has all the information
to create a local frame

```
def curry2(f):
```

```
    """Returns a function g such that g(x)(y) returns f(x, y)."""
```

```
    def g(x):
```

```
        def h(y):
```

```
            return f(x, y)
```

```
        return h
```

```
    return g
```

Currying: Transforming a multi-argument
function into a single-argument,
higher-order function.

Anatomy of a recursive function:

- The **def statement header** is similar to other functions
- Conditional statements check for **base cases**
- Base cases are evaluated **without recursive calls**
- Recursive cases are evaluated **with recursive calls**

```
def sum_digits(n):
    """Return the sum of the digits of positive integer n."""
    if n < 10:
        return n
    else:
        all_but_last, last = n // 10, n % 10
        return sum_digits(all_but_last) + last
```

Program output:

```
123
12
1
12
```

```
1 def inverse_cascade(n):
```

```
12 grow(n)
```

```
123 shrink(n)
```

```

```
123     f(n)
```

```
123     g(n)
```

```
1 grow = lambda n: f_then_g(grow, print, n//10)
1 shrink = lambda n: f_then_g(print, shrink, n//10)
```

```
n: 0, 1, 2, 3, 4, 5, 6, 7, 8,
fib(n): 0, 1, 1, 2, 3, 5, 8, 13, 21,

def fib(n):
    if n == 0:
        return 0
    elif n == 1:
        return 1
    else:
        return fib(n-2) + fib(n-1)
```

square = lambda x: x * x

VS

```
def square(x):
    return x * x
```

- Both create a function with the same domain, range, and behavior.
- Both functions have as their parent the environment in which they were defined.
- Both bind that function to the name `square`.
- Only the `def` statement gives the function an intrinsic name.

When a function is defined:

1. Create a **function value**: `func <name>(<formal parameters>)`
2. Its parent is the current frame.

```
f1: make_adder      func adder(k) [parent=f1]
```

3. Bind **<name>** to the **function value** in the current frame (which is the first frame of the current environment).

When a function is called:

1. Add a **local frame**, titled with the **<name>** of the function being called.
2. Copy the parent of the function to the **local frame**: `[parent=<label>]`
3. Bind the **<formal parameters>** to the arguments in the **local frame**.
4. Execute the body of the function in the environment that starts with the **local frame**.

```
1 def fact(n):
2     if n == 0:
3         return 1
4     else:
5         return n * fact(n-1)
6
7 fact(3)
```

Global frame

func fact(n) [parent=Global]

fact

f1: fact [parent=Global]

n 3

Return value 6

f2: fact [parent=Global]

n 2

Return value 2

f3: fact [parent=Global]

n 1

Return value 1

f4: fact [parent=Global]

n 0

Return value 1

Is `fact` implemented correctly?

1. Verify the base case.
2. Treat `fact` as a functional abstraction!
3. Assume that `fact(n-1)` is correct.
4. Verify that `fact(n)` is correct, assuming that `fact(n-1)` correct.

- Recursive decomposition: finding simpler instances of a problem.

- E.g., `count_partitions(6, 4)`

- Explore two possibilities:

- Use at least one 4

- Don't use any 4

- Solve two simpler problems:

- `count_partitions(2, 4)`

- `count_partitions(6, 3)`

- Tree recursion often involves exploring different choices.

```
def count_partitions(n, m):
```

```
    if n == 0:
```

```
        return 1
```

```
    elif n < 0:
```

```
        return 0
```

```
    elif m == 0:
```

```
        return 0
```

```
    else:
```

```
        with_m = count_partitions(n-m, m)
```

```
        without_m = count_partitions(n, m-1)
```

```
        return with_m + without_m
```

```
from operator import floordiv, mod
```

```
def divide_exact(n, d):
```

```
    """Return the quotient and remainder of dividing N by D.
```

```
>>> q, r = divide_exact(2012, 10)
```

```
>>> q
```

```
201
```

```
>>> r
```

```
2
```

```
"""
```

```
return floordiv(n, d), mod(n, d)
```

Multiple assignment
to two namesMultiple return values,
separated by commas

Numeric types in Python:

```
>>> type(2)
<class 'int'>
```

Represents integers exactly

```
>>> type(1.5)
<class 'float'>
```

Represents real numbers approximately

```
>>> type(1+1j)
<class 'complex'>
```

Functional pair implementation:

```
def pair(x, y):
    """Return a functional pair."""
    def get(index):
        if index == 0:
            return x
        elif index == 1:
            return y
    return get
```

This function represents a pair

```
def select(p, i):
    """Return element i of pair p."""
    return p(i)
```

Constructor is a higher-order function

Selector defers to the object itself

```
>>> p = pair(1, 2)
>>> select(p, 0)
1
>>> select(p, 1)
2
```

Lists:

```
>>> digits = [1, 8, 2, 8]
>>> len(digits)
4
>>> digits[3]
8
```

list

```
>>> [2, 7] + digits * 2
[2, 7, 1, 8, 2, 8, 1, 8, 2, 8]
```

```
>>> pairs = [[10, 20], [30, 40]]
>>> pairs[1]
[30, 40]
>>> pairs[1][0]
30
```

list

Executing a for statement:

```
for <name> in <expression>:
    <suite>
```

1. Evaluate the header `<expression>`, which must yield an iterable value (a sequence)
2. For each element in that sequence, in order:
 - A. Bind `<name>` to that element in the current frame
 - B. Execute the `<suite>`

Unpacking in a for statement:

A sequence of fixed-length sequences

```
>>> pairs = [[1, 2], [2, 2], [3, 2], [4, 4]]
>>> same_count = 0
```

```
>>> for x, y in pairs:
...     if x == y:
...         same_count = same_count + 1
>>> same_count
2
```

A name for each element in a fixed-length sequence

```
..., -3, -2, -1, 0, 1, 2, 3, 4, ...
```

range(-2, 2)

Length: ending value – starting value

Element selection: starting value + index

```
>>> list(range(-2, 2))
[-2, -1, 0, 1]
```

List constructor

```
>>> list(range(4))
[0, 1, 2, 3]
```

Range with a 0 starting value

Membership:

```
>>> digits = [1, 8, 2, 8]
>>> 2 in digits
True
>>> 1828 not in digits
True
```

Slicing:

```
>>> digits[0:2]
[1, 8]
>>> digits[1:]
[8, 2, 8]
```

Slicing creates a new object

List comprehensions:

```
[<map exp> for <name> in <iter exp> if <filter exp>]
```

Short version: `[<map exp> for <name> in <iter exp>]`

A combined expression that evaluates to a list using this evaluation procedure:

1. Add a new frame with the current frame as its parent
2. Create an empty *result list* that is the value of the expression
3. For each element in the iterable value of `<iter exp>`:
 - A. Bind `<name>` to that element in the new frame from step 1
 - B. If `<filter exp>` evaluates to a true value, then add the value of `<map exp>` to the result list

```
def apply_to_all(map_fn, s):
    """Apply map_fn to each element of s.
    0, 1, 2, 3, 4
    """
    >>> apply_to_all(lambda x: x*3, range(5))
    [0, 3, 6, 9, 12]
    return [map_fn(x) for x in s]
    0, 3, 6, 9, 12

def keep_if(filter_fn, s):
    """List elements x of s for which
    filter_fn(x) is true.
    0, 1, 2, 3, 4,
    5, 6, 7, 8, 9
    """
    >>> keep_if(lambda x: x>5, range(10))
    [6, 7, 8, 9]
    return [x for x in s if filter_fn(x)]
    6, 7, 8, 9
```

```
def reduce(reduce_fn, s, initial):
    """Combine elements of s pairwise using reduce_fn,
    starting with initial.
    """
```

```
r = initial
for x in s:
    r = reduce_fn(r, x)
return r
```

Diagram illustrating the reduction process for the list [1, 2, 3, 4] with initial value 16,777,216. The process involves repeatedly applying a function (pow) to the current result and the next element in the list.

Type dispatching: Look up a cross-type implementation of an operation based on the types of its arguments. Type coercion: Look up a function for converting one type to another, then apply a type-specific implementation.

$\Theta(b^n)$ Exponential growth. Recursive fib takes $\Theta(\phi^n)$ steps, where $\phi = \frac{1+\sqrt{5}}{2} \approx 1.61828$. Incrementing the problem size n by a factor of k increases $R(n)$ by a factor of k^2 .

$\Theta(n^2)$ Quadratic growth. E.g., `overlap`. Incrementing n increases $R(n)$ by the problem size n .

$\Theta(n)$ Linear growth. E.g., `factors` or `exp`.

$\Theta(\log n)$ Logarithmic growth. E.g., `exp_fast`.

$\Theta(1)$ Doubling the problem only increments $R(n)$.

Constant. The problem size doesn't matter.

Global frame

```
func make_withdraw(balance) [parent=Global]
    make_withdraw
    withdraw
    >>> withdraw = make_withdraw(100)
    >>> withdraw(25)
    75
    >>> withdraw(25)
    50
    def make_withdraw(balance):
        def withdraw(amount):
            nonlocal balance
            if amount > balance:
                return 'No funds'
            balance = balance - amount
            return balance
        return withdraw
```

The parent frame contains the balance of withdraw

Every call decreases the same balance

f1: make_withdraw [parent=Global]

f2: withdraw [parent=f1]

f3: withdraw [parent=f1]

Strings as sequences:

```
>>> city = 'Berkeley'
>>> len(city)
8
>>> city[3]
'k'
>>> 'here' in "Where's Waldo?"
True
>>> 234 in [1, 2, 3, 4, 5]
False
>>> [2, 3, 4] in [1, 2, 3, 4]
False
```

List & dictionary mutation:

```
>>> a = [10]
>>> b = a
>>> a == b
True
>>> a.append(20)
>>> a == b
True
>>> a
[10, 20]
>>> b
[10, 20]
>>> a == b
False
```

```
>>> nums = {'I': 1.0, 'V': 5, 'X': 10}
>>> nums['X']
10
>>> nums['I'] = 1
>>> nums['L'] = 50
>>> nums
{'X': 10, 'L': 50, 'V': 5, 'I': 1}
>>> sum(nums.values())
66
>>> dict([(3, 9), (4, 16), (5, 25)])
{3: 9, 4: 16, 5: 25}
>>> nums.get('A', 0)
0
>>> nums.get('V', 0)
5
>>> {x: x*x for x in range(3,6)}
{3: 9, 4: 16, 5: 25}
>>> suits = ['coin', 'string', 'myriad']
>>> original_suits = suits
>>> suits.pop()
'myriad'
>>> suits.remove('string')
>>> suits.append('cup')
>>> suits.extend(['sword', 'club'])
>>> suits[2] = 'spade'
>>> suits
['coin', 'cup', 'spade', 'club']
>>> suits[0:2] = ['heart', 'diamond']
>>> suits
['heart', 'diamond', 'spade', 'club']
>>> original_suits
['heart', 'diamond', 'spade', 'club']
```

Identity:

`<exp0> is <exp1>` evaluates to `True` if both `<exp0>` and `<exp1>` evaluate to the same object

Equality:

`<exp0> == <exp1>` evaluates to `True` if both `<exp0>` and `<exp1>` evaluate to equal values

Identical objects are always equal values

You can copy a list by calling the list constructor or slicing the list from the beginning to the end.

Constants: Constant terms do not affect the order of growth of a process

$\Theta(n)$ $\Theta(500 \cdot n)$ $\Theta(\frac{1}{500} \cdot n)$

Logarithms: The base of a logarithm does not affect the order of growth of a process

$\Theta(\log_2 n)$ $\Theta(\log_{10} n)$ $\Theta(\ln n)$

Nesting: When an inner process is repeated for each step in an outer process, multiply the steps in the outer and inner processes to find the total number of steps

```
def overlap(a, b):
    count = 0
    for item in a:
        if item in b:
            count += 1
    return count
```

Outer: length of a

Inner: length of b

If a and b are both length n , then `overlap` takes $\Theta(n^2)$ steps

Lower-order terms: The fastest-growing part of the computation dominates the total

$\Theta(n^2)$ $\Theta(n^2 + n)$ $\Theta(n^2 + 500 \cdot n + \log_2 n + 1000)$

Status	Effect
•No nonlocal statement	Create a new binding from name "x" to number 2 in the first frame of the current environment
•"x" is not bound locally	
•No nonlocal statement	Re-bind name "x" to object 2 in the first frame of the current environment
•"x" is bound locally	
•nonlocal x	
•"x" is bound in a non-local frame	Re-bind "x" to 2 in the first non-local frame of the current environment in which "x" is bound
•nonlocal x	
•"x" is not bound in a non-local frame	SyntaxError: no binding for nonlocal 'x' found
•nonlocal x	
•"x" is bound in a non-local frame	SyntaxError: name 'x' is parameter and nonlocal
•"x" also bound locally	

Linked list data abstraction:

```

empty = 'empty'

def partitions(n, m):
    """Return a linked list of partitions
    of n using parts of up to m.
    Each partition is a linked list.
    """
    if n == 0:
        return link(empty, empty)
    elif n < 0:
        return empty
    elif m == 0:
        return empty
    else:
        # Do I use at least one m?
        yes = partitions(n-m, m)
        no = partitions(n, m-1)
        add_m = lambda s: link(m, s)
        yes = apply_to_all_link(add_m, yes)
        return extend(yes, no)

def link(first, rest):
    return [first, rest]

def first(s):
    return s[0]

def rest(s):
    return s[1]

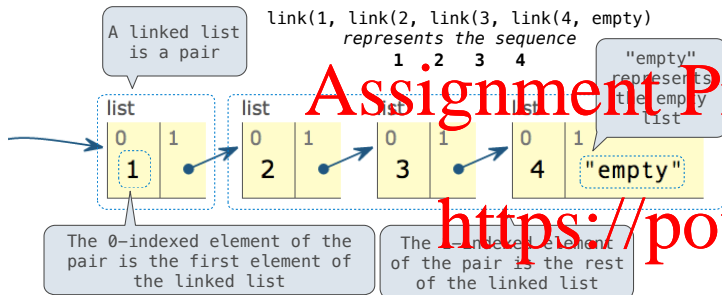

def len_link(s):
    x = 0
    while s != empty:
        s, x = rest(s), x+1
    return x

def getitem_link(s, i):
    while i > 0:
        s, i = rest(s), i-1
    return first(s)

def extend(s, t):
    assert is_link(s) and is_link(t)
    if s == empty:
        return t
    else:
        return link(first(s), extend(rest(s), t))

def apply_to_all_link(f, s):
    if s == empty:
        return s
    else:
        return link(f(first(s)), apply_to_all_link(f, rest(s)))

```

The result of calling `repr` on a value is what Python prints in an interactive session. The result of calling `str` on a value is what Python prints using the `print` function.

```

>>> 12e12
12000000000000.0
>>> print(repr(12e12))
12000000000000.0
>>> print(today)
2014-10-13

```

`str` and `repr` are both polymorphic; they apply to any object. `repr` invokes a zero-argument method `__repr__` on its argument.

```

>>> today.__repr__()
'datetime.date(2014, 10, 13)'
>>> today.__str__()
'2014-10-13'

```

class `Link`:
`empty = ()` Some zero length sequence

```

def __init__(self, first, rest=empty):
    self.first = first
    self.rest = rest
def __getitem__(self, i):
    if i == 0:
        return self.first
    else:
        return self.rest[i-1]
def __len__(self):
    return 1 + len(self.rest)

```

Sequence abstraction special names:
`__getitem__` Element selection []
`__len__` Built-in len function

```

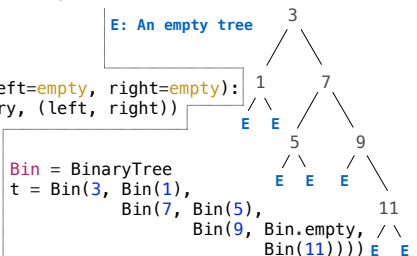

class Tree:
    def __init__(self, entry, branches=()):
        self.entry = entry
        for branch in branches:
            assert isinstance(branch, Tree)
        self.branches = list(branches)

```

```

class BinaryTree(Tree):
    empty = Tree(None)
    empty.is_empty = True
    def __init__(self, entry, left=empty, right=empty):
        Tree.__init__(self, entry, (left, right))
        self.is_empty = False
    @property
    def left(self):
        return self.branches[0]
    @property
    def right(self):
        return self.branches[1]

```

Python object system:

Idea: All bank accounts have a `balance` and an account `holder`; the `Account` class should add those attributes to each of its instances.

A new instance is created by calling a class

```

>>> a = Account('Jim')
>>> a.holder
'Jim'
>>> a.balance
0

```

An account instance

balance: 0 holder: 'Jim'

When a class is called:

1. A new instance of that class is created:
2. The `__init__` method of the class is called with the new object as its first argument (named `self`), along with any additional arguments provided in the call expression.

```

class Account:
    def __init__(self, account_holder):
        self.balance = 0
        self.holder = account_holder
    def deposit(self, amount):
        self.balance = self.balance + amount
        return self.balance
    def withdraw(self, amount):
        if amount > self.balance:
            return 'Insufficient funds'
        self.balance = self.balance - amount
        return self.balance

```

`__init__` is called a constructor

`self` should always be bound to an instance of the `Account` class or a subclass of `Account`

Function call: all arguments within parentheses

```

>>> type(Account.deposit)
<class 'function'>
>>> type(a.deposit)
<class 'method'>

```

Method invocation: One object before the dot and other arguments within parentheses

```

>>> Account.deposit(a, 5)
10
>>> a.deposit(2)
12

```

Call expression

Dot expression

Memoization:

```

def memoized(f):
    cache = {}
    def memoized(n):
        if n not in cache:
            cache[n] = f(n)
        return cache[n]
    return memoized

```

The `<expression>` can be an arbitrary Python expression. The `<name>` must be a simple name. Evaluates to the value of the attribute looked up by `<name>` in the object that is the value of the `<expression>`.

To evaluate a dot expression:

1. Evaluate the `<expression>` to the left of the dot, which yields the object of the dot expression.
2. `<name>` matches against the instance attributes of that object; if an attribute with that name exists, its value is returned.
3. If not, `<name>` is looked up in the class, which yields a class attribute value.
4. That value is returned unless it is a function, in which case a bound method is returned instead.

Assignment statements with a dot expression on their left-hand side affect attributes for the object of that dot expression.

- If the object is an instance, then assignment sets an instance attribute.
- If the object is a class, then assignment sets a class attribute.

Account class attributes

interest: 0.02, 0.04, 0.05
(withdraw, deposit, `__init__`)

Instance attributes of jim_account

balance: 0
holder: 'Jim'
interest: 0.08

Instance attributes of tom_account

balance: 0
holder: 'Tom'

```

>>> jim_account = Account('Jim')
>>> tom_account = Account('Tom')
>>> tom_account.interest
0.02
>>> jim_account.interest
0.02
>>> Account.interest = 0.04
>>> tom_account.interest
0.04
>>> jim_account.interest
0.04
>>> Account.interest = 0.05
>>> tom_account.interest
0.05
>>> jim_account.interest
0.08

```

class `CheckingAccount`(`Account`):

"""A bank account that charges for withdrawals."""

withdraw_fee = 1

interest = 0.01

def `withdraw`(`self`, `amount`):

return `Account.withdraw`(`self`, `amount` + `self.withdraw_fee`)
or
return `super().withdraw`(`amount` + `self.withdraw_fee`)

To look up a name in a class:

1. If it names an attribute in the class, return the attribute value.
2. Otherwise, look up the name in the base class, if there is one.

```

>>> ch = CheckingAccount('Tom') # Calls Account.__init__
>>> ch.interest # Found in CheckingAccount
0.01
>>> ch.deposit(20) # Found in Account
20
>>> ch.withdraw(5) # Found in CheckingAccount
14

```
